Under certain conditions, a fermion in a superconductor can separate in space into two parts known as Majorana zero modes, which are immune to decoherence from local noise sources and are attractive building blocks for quantum computers. Promising experimental progress has been made to demonstrate Majorana zero modes in materials with strong spin–orbit coupling proximity coupled to superconductors. Here we report signatures of Majorana zero modes in a material platform utilizing the surface states of gold. Using scanning tunneling microscopy to probe EuS islands grown on top of gold nanowires, we observe two well-separated zero-bias tunneling conductance peaks aligned along the direction of the applied magnetic field, as expected for a pair of Majorana zero modes. This platform has the advantage of having a robust energy scale and the possibility of realizing complex designs using lithographic methods.

Majorana zero mode | topological superconductor | quantum computing | Majorana bound state

Majorana zero modes (MZMs) are fermionic states, each of which is an antiparticle of itself. MZMs are required to always appear in pairs (1). Each MZM pair has the degrees of freedom of a single fermion, which is split nonlocally in space into two MZMs. The nonlocality implies that MZMs are immune to local perturbations, and hence they have been proposed as the key ingredients of topological qubits that are protected from decoherence due to local noise sources (1, 2). MZMs are predicted to exist in certain topological superconductors (TSCs). Up to now, various proposals have been made to engineer TSCs by combining conventional materials (3–9), and great progress has been made toward revealing the signatures of MZMs (10–29). Here we report the observations of signatures of MZMs in the form of zero-bias peaks (ZBP) in a platform which is based on the surface state of gold (Au). Our metal-based platform holds a number of advantages. First, there is a wealth of experience in epitaxial growth of noble metals on a variety of superconductors (30–32), as well as epitaxial growth of ferromagnetic insulators on top (33). Second, lithographic methods to produce large arrays of increasingly complex designs are well-developed. Finally, the energy scales in a metal are generally high compared with those of semiconductors. While the eventual goal of producing a topological qubit-based quantum computer is still daunting, our work opens a vision of a path forward.

Our platform is based on the Shockley surface state (SS) of Au(111) with induced superconductivity (33), as proposed theoretically several years ago (34). An important motivation of using the SS of Au(111) is its large Rashba spin–orbit coupling energy scale leading to a splitting of 110 meV (35, 36), which is several orders of magnitude larger than those in semiconductor nanowires. A schematic drawing of the needed heterostructure is shown in Fig. 1A. An Au film is grown on top of a superconductor (vanadium [V] in our case) and the bulk Au becomes superconducting due to the proximity effect. The bulk Au in turn induces a pairing gap on the SS. We have shown earlier that the SS has an energy gap of 0.38 meV, distinct from the bulk Au gap, which is 0.61 meV (33). On top of Au we grow an epitaxial film of EuS, a ferromagnetic insulator to magnetize the Au SS via exchange coupling. We have created arrays of Au(111) wires (Fig. 1B and Fig. 2A) utilizing our epitaxially grown thin film layers and nanolithography (32, 33). The wires are 4 nm thick, ∼100 nm wide or less, and microns in length as seen in Fig. 1B and C. We emphasize that our Au(111) wires are highly crystalline with sharp edges (Fig. 1C). The scanning tunneling spectroscopy (STS) spectrum shows clearly that a hard superconducting gap is induced in the Au wire from the V underneath (see Figs. 1D, 3A, and 4D). The Au wire is homogeneously in contact with the V layer sharing a high-quality interface that is made under ultrahigh vacuum environment (Fig. 1A and see Methods). However, the proposal based on the SS of Au(111) has a serious limitation. The bottom of the SS band lies about 500 meV below the Fermi level (35–37). For a 100-nm-wide Au wire, this means that there are ∼100 transverse subbands crossing the Fermi level. Our theory simulations show that the topological state is extremely delicate under such a condition, and it is unlikely that the MZMs have detectable signals (SI Appendix, section 3). Another limitation is the need for a large parallel magnetic field to

Significance

In 1937 Ettore Majorana pointed out that unlike the standard solution of the Dirac equation which leads to the electron and its antiparticle, the positron, it is possible to have a solution where the fermionic particle is its own antiparticle. While such a particle remains elusive in particle physics, a pair of localized Majorana states has been predicted to reside at the ends of a specially designed superconducting wire. These Majorana zero modes can form building blocks of qubits for fault-tolerant quantum computers. Here we report signatures of Majorana zero modes in a platform consisting of EuS and gold films grown on vanadium. This platform is amenable to standard nanofabrication techniques and holds promise for scalable Majorana qubits.

overcome the induced superconducting gap (see Figs. 1D, 3A, and 4D), which is much larger compared to platforms based on semiconductors with large g-factors.

We overcome the above limitations by depositing a thin layer of EuS onto the Au wires, which has been shown to be effective in dramatically lowering the Fermi level of SS (33). In addition, EuS is a ferromagnetic insulator, known to induce sizeable magnetic exchange field in adjoining layers, thereby reducing the need for a large applied magnetic field (38–41). Fig. 2D shows that two monolayers (MLs) of EuS deposited on the Au wire (Fig. 2A–C) is enough to shift the bottom of the SS band all the way to only ∼30 meV below the Fermi level. We ascertain this by performing a series of STS scans along the surface of an Au nanowire and comparing them with similar scans on top of a two MLs EuS island. The STS peak marked by an arrow is the signature of the band bottom of SS, characterized by a square root singularity of the density of states. The STS peak of the pristine Au nanowire surface is at about 420 meV below the Fermi energy, consistent with the values reported by angle-resolved photoemission spectroscopy (35, 36) and STS (37). We define the chemical potential μ as the energy difference between the Fermi level and the crossing point of the Rashba bands, which lies 15 meV above the band bottom. We conclude that two MLs of EuS places the chemical potential μ to be about 15 meV. This means that for a 100-nm-wide wire only about five transverse subbands cross the Fermi level and the condition for creating MZM is much more favorable (SI Appendix, sections 4 and 5).

If a middle segment of the Au wire is completely covered by EuS, two MZMs are expected to emerge underneath the ends of the EuS in the presence of a magnetic field applied parallel to the wire. Unfortunately, STS probe of the Au SS through two MLs of EuS can only be done with low energy resolution. While a
continuous EuS layer can be grown to completely cover the surface of an Au wire when a thick layer of EuS is deposited, we find that EuS islands that are uniformly two MLs thick can be formed when the EuS coverage is low (Fig. 2C). Although planar tunnel junctions can be used to tunnel through a thick EuS layer (33), as a proof of concept we focus on EuS islands and use STS for the tunneling measurements (Fig. 2C). In order to obtain high-resolution STS, we tunnel into the exposed Au(111) surface regions in the vicinity of an EuS island ~2 nm away from the island edge. Fig. 1A shows a schematic of such measurements. If MZMs emerge underneath the EuS island, the scanning tunneling microscope (STM) tip can still couple to the MZMs due to their spatial decay (Fig. 1B). The decay length is found to be about 8 nm (SI Appendix; section 8), so 2 nm is well within the decay length.

We found ZBPs emerging inside the pairing gap when an applied magnetic field exceeds a certain value. Fig. 3 shows the tunneling spectra taken at a number of positions around an island about 30 nm wide and 25 nm long sitting on an Au nanowire (Fig. 2C). At zero field, the dI/dV spectra demonstrate a hard superconducting gap, which does not change regardless of the location where the STS is taken (Fig. 3A and 4D). The results demonstrate a uniformly induced superconductivity in Au(111), and the shape of the EuS island has no effect on the induced gap. With a 4.8-T magnetic field applied along the wire (called the north–south direction), a ZBP appears in positions 1, 2, and 3 near the north side of the island and near position 6 on the opposite side (Fig. 3B). On the other hand, anywhere in between these positions the tunneling spectra remain largely unchanged except for a small filling in the gap due to the applied magnetic field (Fig. 3A). To visualize the evolution of the gap and the ZBP, that is, to demonstrate the topological transition, we take the STS data with a fine scan of the magnetic field near position 6 (Fig. 2C). In a two-dimensional density plot, a transition characterized by the closing of the superconducting gap and the emergence of ZBP beyond a critical field value is observed (Fig. 3C). The line scans (Fig. 3D) show that the superconducting gap evolves from a “U” to a “V” shape before the gap is filled in and the ZBP emerges after that. As we shall see, these features closely resemble the topological transition in a multimode system modeled by our theory (Fig. 6C).

We note that the width of the ZBP is about 0.2 meV, about a factor 2 larger than 2kBT that is expected for the temperature of 0.38 K. The width is limited by the instrumental resolution due to the bias modulation voltage needed to achieve a signal with a sufficiently low noise (Methods). Therefore, it is possible that the ZBPs are due to a pair of MZMs which are hybridized to give a pair of split peaks that are not resolved. In fact, such splitting is to be expected for an island that is so small.

We next show results on a more rectangularly shaped island (60 nm × 45 nm) with an edge which overlaps the edge of the Au(111) wire as shown in Fig. 4B. The EuS island has excellent crystalline quality as can be seen from the atomically resolved STM image (Fig. 4C). We apply a magnetic field parallel to the wire and take STS measurements in the exposed Au(111) regions around the island. Again, we find uniform and fully gapped spectra at zero field (Fig. 4D). In a 4.8-T field, two ZBPs are observed on the opposite sides of the EuS island at the positions where the island intersects the edge of the Au wire (Fig. 4B and E). At all other positions (labeled 2 through 7), the superconducting gap spectra remain unchanged except for a slight filling of the gap. Apparently the wavefunction corresponding to the ZBPs is strongly localized along the intersected edge of the EuS island and the Au nanowire, rather than spread out along the upper and lower edges of the EuS island. This observation is also found in our simulations discussed below, as shown in Fig.
The weight of the ZBP is reduced by the factor \( \Gamma_p \). Since \( \Gamma \) is very small for STM tunneling, a large reduction of the ZBP weight is expected near the topological transition at around 3.5 T. The weight gradually increases as the magnetic field of more than 0.5 T. We note that a sharp closing and the emergence of MZMs take place rather gradually below and supported by simulations shown in Fig. 6, the gap closing and the emergence of the MZM take place rather gradually due to a multitude of low-lying states near the threshold. The second reason has to do with quasi-particle poisoning due to excitations above the topological gap (Fig. 5B), which is defined as the energy of the lowest extended quasi-particles state. This gap closes at the topological transition and reopens at higher fields, so that just above the transition we expect a large poisoning rate \( \Gamma_p \). The weight of the ZBP is reduced by the factor \( \Gamma/\Gamma_p \), where \( \Gamma \) is the tunneling rate (42). Since \( \Gamma \) is the tunneling rate (42). Since \( \Gamma \) is very small for STM tunneling, a large reduction of the ZBP weight is expected near the topological transition at around 3.5 T. The weight gradually increases as the topological gap reopens and \( \Gamma_p \) is reduced. Since \( \Gamma \) and \( \Gamma_p \) depend on the local details near the location of the MZM, the visibility and the onset magnetic field of each MZM partner is expected to have some variation, consistent with Fig. 4 F and G.

To support our interpretation, we have carried out numerical simulations on realistic models of the Au(111) wire partially covered by EuS. We perform the calculation on a square lattice with hopping and Rashba energies chosen to match the band structure of the Au SSs. We allow the chemical potential to be reduced and the effective Zeeman energy \( V_z \) to be enhanced under the EuS island. The coupling between the SS and the bulk Au states has been taken into account with a self-energy correction (SI Appendix, section 1). Indeed, we found that when the chemical potential under EuS is less than \( 30 \) meV, the MZMs exist over a large fraction of the chemical potential range with a relatively large gap to other subgap excitations, so that the chance of finding robust MZMs is quite high (SI Appendix, Fig. S2 B and C). The spectrum and the distribution of the wavefunction are shown in Fig. 5 for an island that is 60 nm \( \times \) 60 nm which overlaps the edge of the Au wire. In Fig. 5A we see that the MZM wavefunctions are strongly localized at the corners of the intersected edge, in excellent agreement with what is seen experimentally in Fig. 4. In contrast, for a rectangularly shaped island that is in the middle of a Au wire and removed from the edge, the MZM wavefunctions are spread out along the north and south edges (SI Appendix, Fig. S3). It is apparent that the MZM wavefunction can be trapped by spatial inhomogeneity such as the proximity to a step in the chemical potential near the edge of the Au wire. A second point we find from the calculation is that the decay length of the MZM perpendicular to the edge

5A. The localization of the MZM is sensitive to the local environment such as steps in the chemical potentials at the edge of the Au wire, thus accounting for the strong localization in this case.

We next study the evolution of ZBPs at positions 1 and 8 as a function of the applied magnetic field (\( H \)). At both positions the gap fills in when \( H \) is around 3.5 T (Fig. 4 F and G), which agrees well with the onset of ZBPs in the other island (Fig. 3C). The ZBP appears at comparable threshold magnetic fields for position 1 (at \( H = 3.5 \) T) and for position 8 (at \( H = 3.4 \) T) (Fig. 4 F and G). The slightly different threshold magnetic fields can be a result of the broad transition region as seen in Fig. 3C. For Fig. 3C, the transition takes place at around 3.5 T but has a blurred region with a span of the magnetic field of more than 0.5 T. We note that a sharp threshold field and the emergence of MZMs simultaneously at the same threshold field are not expected under our experimental conditions. There are two reasons. The first is that, unlike the quantum wire case, we are in a multimode situation. As explained below and supported by simulations shown in Fig. 6, the gap closing and the emergence of the MZM take place rather gradually due to a multitude of low-lying states near the threshold. The second reason has to do with quasi-particle poisoning due to excitations above the topological gap (Fig. 5B), which is defined as the energy of the lowest extended quasi-particles state. This gap closes at the topological transition and reopens at higher fields, so that just above the transition we expect a large poisoning rate \( \Gamma_p \). The weight of the ZBP is reduced by the factor \( \Gamma/(\Gamma + \Gamma_p) \), where \( \Gamma \) is the tunneling rate (42). Since \( \Gamma \) is very small for STM tunneling, a large reduction of the ZBP weight is expected near the topological transition at around 3.5 T. The weight gradually increases as the topological gap reopens and \( \Gamma_p \) is reduced. Since \( \Gamma \) and \( \Gamma_p \) depend on the local details near the location of the MZM, the visibility and the onset magnetic field of each MZM partner is expected to have some variation, consistent with Fig. 4 F and G.

To support our interpretation, we have carried out numerical simulations on realistic models of the Au(111) wire partially covered by EuS. We perform the calculation on a square lattice with hopping and Rashba energies chosen to match the band structure of the Au SSs. We allow the chemical potential to be reduced and the effective Zeeman energy \( V_z \) to be enhanced under the EuS island. The coupling between the SS and the bulk Au states has been taken into account with a self-energy correction (SI Appendix, section 1). Indeed, we found that when the chemical potential under EuS is less than \( 30 \) meV, the MZMs exist over a large fraction of the chemical potential range with a relatively large gap to other subgap excitations, so that the chance of finding robust MZMs is quite high (SI Appendix, Fig. S2 B and C). The spectrum and the distribution of the wavefunction are shown in Fig. 5 for an island that is 60 nm \( \times \) 60 nm which overlaps the edge of the Au wire. In Fig. 5A we see that the MZM wavefunctions are strongly localized at the corners of the intersected edge, in excellent agreement with what is seen experimentally in Fig. 4. In contrast, for a rectangularly shaped island that is in the middle of a Au wire and removed from the edge, the MZM wavefunctions are spread out along the north and south edges (SI Appendix, Fig. S3). It is apparent that the MZM wavefunction can be trapped by spatial inhomogeneity such as the proximity to a step in the chemical potential near the edge of the Au wire. A second point we find from the calculation is that the decay length of the MZM perpendicular to the edge
Fig. 4. (A) The STM topography image of another Au(111) nanowire array (similar to that in Fig. 2A) with two MLs of EuS deposited over it \(V_{\text{sample}} = 1.6\ \text{V}, I_{\text{set}} = 46\ \text{pA}, T = 0.38\ \text{K}\). The applied magnetic field is aligned with the nanowire to the best accuracy of our STM setup. (B) The zoomed-in STM topography image \(75 \times 75\ \text{nm}^2, V_{\text{sample}} = 1\ \text{V}, I_{\text{set}} = 0.5\ \text{pA}\) of a relatively large EuS island sitting at the edge of the Au nanowire in A. The island is \(\sim 40\ \text{nm}\) long along the wire and \(60\ \text{nm}\) wide. (C) The atomically resolved \((4 \times 4\ \text{nm}^2, V_{\text{sample}} = 120\ \text{mV}, I_{\text{set}} = 600\text{pA})\) EuS surface in the marked region as noted in B. (D) The comparison of the dI/dV tunneling spectra under both \(H = 0\ \text{T}\) and \(H = 4.8\ \text{T}\). Dashed lines mark the zero conductance of each shifted spectrum. The spectra at all positions are gapped when \(H = 0\ \text{T}\). A slight filling in of the gap is seen at positions 2 through 7 in the 4.8-T field. (E) Sharp ZBP emerges for \(H = 4.8\ \text{T}\) at positions 1 and 8. Curve 8 is shifted vertically by two tick marks. The zero conductance for each curve is noted with the same color as the curve. (F and G) The evolution of the dI/dV spectra at position 1 and 8 as a function of the strength of the applied field. At 3.5 T the gap is largely filled in at positions 1 and 8 simultaneously. The ZBP is visible at 3.5 T at position 1 and at 4 T at position 8. At 4-T field and above, the ZBPs at positions 1 and 8 show comparable peak heights. All of the dI/dV spectra in D–G are normalized to the normal-state conductance.

We note that much of the literature deals with the case with a single transverse mode which is relevant to the semiconductor nanowires. Here we highlight the difference with the multimode situation that is relevant to our system. To make the physics clearer, we focus on a longer island that is \(60\ \text{nm} \times 300\ \text{nm}\) where the energy splitting of the MZMs is small and well-separated from the higher-energy states. Fig. 6a shows the lowest 25 eigenvalues as a function of the effective Zeeman energy \(V_Z\). We see that the gap defined by the lowest excited state closes at \(V_Z = 1.1\ \Delta_0\) and reopens, leaving behind a pair of split MZMs. The topological gap that reopens is about \(0.2\ \Delta_0\). Note that a large number of states come down in energy as the gap closes and a large number lie above the topological gap that reopens. Consequently, the contribution of an individual state to the tunneling conductance is very small. In the single-mode case the number of states that come down as the gap closes is much fewer, depending on the sample length, and can even be a single state for short wires (SI Appendix, Fig. S2 F and G). As a result, the gap closing as the topological state is approached can be seen both in experiment and simulation in short nanowires (23). In contrast, in our case the lowest state that leads to gap closing as the threshold is approached contributes only a small amount to the tunneling conductance (Fig. 6a). Upon thermal smearing, we expect a subtle filling in of the gap which becomes V-shaped, as clearly toward the middle of the wire is very short. This explains the surprising fact that ZBPs were observed for islands as small as 30 nm in diameter. The coherence length is short for two reasons. First, the Fermi velocity is very small because we are considering the last filled subband, which has a very small Fermi energy. Second, this situation is similar to what was observed in the Fe atomic chain (16), where the wavefunction leaks into the substrate, giving rise to a reduction of the spectral weight and the velocity, thereby reducing the effective coherence length (43). In fact, this leakage is needed to produce a surface superconducting gap close to the bulk superconducting gap \(\Delta_0\) (34). A key ingredient in the simulation is the assumption of an exchange field under the EuS in addition to the applied magnetic field. Without this, a magnetic field large enough to drive the system to a topological regime also closes the superconducting gap outside and the MZMs will be destroyed. In EuS the magnetic moment normally lies in-plane, but on certain surfaces it is known to develop a canted magnetization with a large out-of-plane component due to spin–orbit coupling (44, 45). In this case the increasing applied parallel magnetic field enhances the Zeeman field along the nanowire due to the canting of the magnetic moment. However, the precise orientation of the magnetic moment in our case is not known.
the gap as the Zeeman field reaches and exceeds the threshold spectra. At 350 mK, we can see a slight and gradual filling in of the 8780 point halfway between where the ZBP appears, and just outside have also examined the tunneling conductance of the Au SS at a point near the edge just outside the EuS, showing a ZBP due to an MZM. The 700-mK curve is chosen to mimic the additional instrumental broadening and can be compared with the experimental curves shown in Fig. 4E. The split peak near zero bias in B is due to the overlap of the MZM localized at opposite ends of the islands. In addition, there are in-gap states which typically start at energy of 0.1 Δk. Thermal smearing picks out these states as sidebands and background, as shown in C and D.

Next, we address the question of whether the ZBP we observed may be due to conventional Andreev bound states that happens to stick to zero energy. Two sources of such Andreev bound states have been discussed depending on whether disorder is present. In the absence of disorder, it has been pointed out that if the end of the wire is subject to a smooth potential, even in the non-topological region a pair of MZMs are often found near the end that are weakly hybridized with each other (46–49). One of these could couple strongly to the outside lead and the tunneling conduction resembles that of a true MZM. The reason for the lack of hybridization is that the two states may have different spins or momenta and are therefore almost orthogonal (48, 49). Such smooth potentials are generic in the semiconductor wire setup because the tunnel barrier is created by gating. In our case, the wire and the island terminate abruptly on an atomic scale and the tunnel barrier is via an STM tip. Therefore, we do not expect this mechanism to be applicable in our system, and indeed we do not see any sign of such false signals in our simulations.

A second source of false signal is that disorder potential may accidentally produce a localized Andreev bound state that happens to have energy near zero. However, such a mechanism usually requires fine-tuning of the parameters. Furthermore, it is equally likely to find such a localized state anywhere along the boundary of the island. This is in contrast to our findings because our ZBPs are aligned with the applied magnetic field and we see no sign of in-gap peaks in zero or finite field anywhere else. Finally, there is no reason why these Andreev bound states will appear at two areas on opposite sides of the same island at a similar magnetic field. In this connection we mention that the appearance of ZBPs in the EuS islands is not a rare occurrence. We have studied about 60 islands under varying experimental conditions which are sometimes not ideal in terms of STM stability. On 20 of these islands we found ZBPs which are always located either near the north or south shore with respect to the magnetic field. We also note that the spectra we see are either fully gapped or exhibit ZBPs and we never find split peaks that may be associated with Andreev bound states. Out of the 20 we saw a pair of ZBPs at opposite ends on four islands, even though in many cases we simply did not explore all the way around the island. In any event, since we do not control the chemical potential, we expect to find MZM less than 50% of the time based on our simulations, consistent with our finding.

Our simulation also found that an EuS island in the middle of a wider Au wire and away from the edges can also support MZMs, even though the wavefunction is more spread out along the edge of the island (SI Appendix, Fig. S3) and thus will be harder to detect with STM. We believe this explains the observation of ZBP localized on the edges of the island shown in Figs. 2 and 3. Importantly, this observation opens the door to the possibility of depositing EuS wires on a large area of Au which will allow even greater freedom in designing more complicated structures toward MZMs based...
topological qubits. Obviously, this is something we plan to explore in the future.

The Au SS platform has a high intrinsic Rashba scale and there is room for further improvement. In the future, by going to planar tunneling an order-of-magnitude reduction in temperature and better energy resolution should be possible. A larger magnetic field can be applied which allows us to utilize superconductors with large gaps, resulting in larger topological gaps. Any coherent manipulation of MZMs requires the topological gap to be much larger than temperature. The Au SS platform holds a lot of promise toward this goal.

The Au/EuS system is amenable to flexible nanofabrication methods. For example, a single topological qubit can be constructed out of two or more wires that are cross-linked, forming “tetrins” or “hexons” that have been proposed to be building blocks of quantum computing circuits (50, 51). An array of such objects can be constructed without too much difficulty (SI Appendix, section 7). In particular, instead of braiding by physically moving MZMs, a measurement-based topological qubit design using a purely superconducting circuit is well-suited with our Au/EuS system (52).

In conclusion, we have found signatures of MZM pairs on a superconducting Au surface as theory predicted. The Au/EuS platform has the advantage of having a robust energy scale and the potential for fabricating a large-scale network. This platform offers a plausible path, though still an extremely challenging one, toward topological quantum computing.

**Methods**

The heterostructures of thin film V(20 nm)/Au(4 nm) are grown in a custom-built molecular beam epitaxy system with a base vacuum $\sim 3.7 \times 10^{-10}$ torr. The growth and characterizations follow procedures similar to those we reported before (32, 33). Au nanowires, or nanoribbons, with a thickness of 4 nm and a wire width around 100 nm (or less) are fabricated after the growth of Au/V heterostructures. The nanowires are sculptured out of the wafer-scale Au thin film by following a standard e-beam lithography and an Ar ion milling process.

![Fig. 6. Simulations for a 60-nm × 300-nm island of EuS that overlaps the edge of a 120-nm-wide Au wire. (A) The lowest 25 eigenvalues plotted vs. the effective Zeeman energy $V_x$. The gap closes near $V_x = 1.1\Delta_B$ and reopens to a topological gap of about 0.2$\Delta_B$. In B and C the tunneling spectra taken near the edge just outside the EuS are shown at $T = 0$, 350 mK and 700 mK. By looking at the $T = 0$ spectra in B we can follow the gap closing as $V_x$ approaches the threshold. The lowest excited state carries a very small weight and is hardly visible. Above the threshold the MZM appears as a double peak split by the overlap in a finite size island. At the same time, the topological gap develops, increasing to 0.2$\Delta_B$ consistent with A. However, a large number of states appear above the topological gap. Further examination shows that some of these states are extended, while others are localized near the ends of the wires, with a wavefunction very similar to that of the MZM. We interpret these states as “Majorana descendants,” a feature of the multiband system as detailed in SI Appendix. Upon thermal averaging, we see in C that at 350 mK the gap closing is indicated by a rather subtle filling in of the gap and the MZM is gradually becoming visible above the threshold effective Zeeman field. The combination of extended states and Majorana descendants give rise to the sidebands of the MZM peak. (C, Right) The 700-mK curves simulate the effect of additional instrumental broadening and can be compared with the measurements shown in Fig. 4 F and G. (D) The tunneling spectra taken at a point near the middle of the wire just outside the EuS boundary. Only the extended states contribute. Note that the gap closing and reopening is hardly observable and is consistent with what is seen in Fig. 4 D, Lower.

Manna et al. PNAS | April 21, 2020 | vol. 117 | no. 16 | 8781
During the nanofabrications, the surface of the superconductor \( V \) is protected in situ using a custom-built high vacuum system (base vacuum \( 10^{-9} \text{ torr} \)) that combines ion milling and thin film evaporation sources, thereby guaranteeing the high quality of the superconductor \( V \). Any shape of nanowire, or a network of nanowires, can be designed by standard e-beam lithography software and fabricated following such an approach (see Appendix, section 7). The surfaces of Au nanowires fabricated in this way are ultraclean, as seen by the atomic resolution images of the STM (Fig. 1). A postgrowth of E\( \delta \) magnetic insulator is carried out in a high vacuum system with a base vacuum \(-10^{-6} \text{ torr} \). The E\( \delta \) growth, from islands to a continuous layer, on Au(111) surface is controllable by varying the E\( \delta \) thickness as described before (33). E\( \delta \) islands are chosen here to align the applied magnetic field with the Au nanowire. Tunneling spectroscopy measurements were taken using a standard lock-in technique at 937-Hz frequency.
